Actris: Session-Type Based Reasoning in Separation Logic

JONAS KASTBERG HINRICHSEN, IT University of Copenhagen, Denmark
JESPER BENGTSON, IT University of Copenhagen, Denmark
ROBBERT KREBBERS, Delft University of Technology, The Netherlands

Message passing is a useful abstraction to implement concurrent programs. For real-world systems, however, it is often combined with other programming and concurrency paradigms, such as higher-order functions, mutable state, shared-memory concurrency, and locks. We present Actris: a logic for proving functional correctness of programs that use a combination of the aforementioned features. Actris combines the power of modern concurrent separation logics with a first-class protocol mechanism—based on session types—for reasoning about message passing in the presence of other concurrency paradigms. We show that Actris provides a suitable level of abstraction by proving functional correctness of a variety of examples, including a distributed merge sort, a distributed load-balancing mapper, and a variant of the map-reduce model, using relatively simple specifications. Soundness of Actris is shown using a continuation-passing style (CPS) interpretation of its protocol mechanism into the Iris framework. We mechanised the theory of Actris, together with tactics for symbolic execution of programs, as well as all examples in the paper, in the Coq proof assistant.

1 INTRODUCTION

Message-passing programs are ubiquitous in modern computer systems, emphasising the importance of their functional correctness. Programming languages, like Erlang, Elixir, and Go, have built-in primitives that handle spawning of processes and intra-process communication, while many other mainstream languages, such as Java, Scala, F#, and C#, have introduced an Actor model [Hewitt et al. 1973] to achieve similar functionality. In both cases the goal remains the same—help design reliable systems, often with close to constant up-time, using lightweight processes that can be spawned by the hundreds of thousands and that communicate via asynchronous message-passing.

While message passing is a useful abstraction, it is by no means a silver bullet of concurrent programming. In a qualitative study of larger Scala projects Tasharofi et al. [2013] write:

We studied 15 large, mature, and actively maintained actor programs written in Scala and found that 80% of them mix the actor model with another concurrency model. For this study, 12 out of 15 projects did not entirely stick to the Actor model, hinting that even for projects that embrace message passing, low-level concurrency primitives like locks (i.e., mutexes) still have their place. Tu et al. [2019] came to a similar conclusion when studying 6 large and popular Go programs. A suitable solution for reasoning about message-passing programs should thus integrate with other programming and concurrency paradigms.

In this paper we introduce Actris—a concurrent separation logic for proving functional correctness of programs that combine message passing with other programming and concurrency paradigms. Actris can be used to reason about programs written in a language that mimics the important features found in aforementioned languages such as higher-order functions, higher-order references, fork-based concurrency, locks, and primitives for asynchronous message passing over channels. The channels of our language are first-class and can be sent as arguments to functions, be sent over other channels (often referred to as delegation), and be stored in references.

Program specifications in Actris are written in an impredicative higher-order concurrent separation logic build on top of the Iris framework [Jung et al. 2016, 2018b, 2015; Krebbers et al. 2017a]. In addition to the usual features of Iris, Actris provides a notion of dependent separation protocols.
to reason about message passing over channels, inspired by the affine variant [Mostrous and Vasconcelos 2014] of binary session types [Honda et al. 1998]. We show that dependent separation protocols integrate seamlessly with other concurrency paradigms, allow delegating linear resources, sharing channels over multiple concurrent threads using locks, and more.

1.1 Message Passing in Concurrent Separation Logic

Proving functional correctness of concurrent programs is known to be notoriously difficult, but significant progress has been made since the seminal development of concurrent separation logic by O’Hearn [2004] and Brookes [2004], which spawned the development of expressive frameworks like TaDA [da Rocha Pinto et al. 2014], iCAP [Svendsen and Birkedal 2014], Iris [Jung et al. 2015], FCSL [Nanevski et al. 2014], and VST [Appel 2014] for reasoning about concurrency.

The primary focus of concurrent separation logic and its descendants has been on reasoning about shared memory concurrency, while there is relatively little work on applying separation logic to message-passing concurrency. Recently, there have been a number of developments applying separation logic to reason about message passing over networks, in particular the Disel logic by Sergey et al. [2018] and the Aneris logic by Krogh-Jespersen et al. [2019]. Being concerned with message passing over networks, where all data has to be serialised, messages can be lost and delivered out of order, these logics naturally deal with message-passing programs at a much lower level of abstraction. Such programs are very different from those found in high-level languages like Erlang, Elixir, Go, and Scala, where one can send messages containing any data type, including functions, references, and channels themselves, and moreover, combine message passing with other concurrency paradigms like lock-based concurrency. However, up to our knowledge, existing work with regard to approaches for reasoning about message passing in high-level languages, e.g., [Francalanza et al. 2011; Lozes and Villard 2012; Oortwijn et al. 2016], do not provide integration with other programming and concurrency paradigms.

An exception is Tassarotti et al. [2017], who used separation logic to verify a small compiler of a message-passing language into a functional language where channel buffers are modelled on the heap. However, their work and many of the other existing approaches [Jung et al. 2015; Krogh-Jespersen et al. 2019; Sergey et al. 2018] make use of some form of State Transition Systems (STS) to model interaction between processes. As a simple example, consider the following program, which is borrowed from Tassarotti et al. [2017]:

\[
\text{prog} \triangleq \text{let } (c, c') = \text{new_chan()} \text{ in fork } \{\text{send } c' \ 42\} ; \text{recv } c
\]

This program creates two channel endpoints \(c\) and \(c'\), forks off a new process, and sends the number 42 over the channel, which is then received by the initiating thread. Modelling the behaviour of this program in an STS typically requires three states:

- **Init**: No message has been sent.
- **Sent**: A message has been sent but not received.
- **Received**: The message has been sent and received.

The three states model that no message has been sent (Init), that a message has been sent but not received (Sent), and finally that the message has been sent and received (Received). Exactly what this STS represents is made precise by the underlying logic, which determines what constitutes a state and a transition, and how these are related to the channel buffers.

While STSs appear like a flexible and intuitive abstraction to reason about message-passing concurrency, they have their problems:

- Coming up with a good STS that makes the appropriate abstractions is difficult because the STS has to keep track of all possible states that the channel buffers can be in, including all possible interleavings of messages being in transit.
• While STSs used for the verification of different modules can be composed at the level of the logic, there is no canonical way of composing them due to their unrestrained structure.
• Finally, STSs are first-order meaning that their states and transitions cannot be indexed by propositions of the underlying logic, which limits what they can express when sending messages containing functions or other channels.

1.2 Dependent Separation Protocols

In this paper we take a different route. Instead of using STSs, we extend separation logic with a new notion called dependent separation protocols. This notion is inspired by the session type community, pioneered by Honda et al. [1998], where channel endpoints are given types that describe the expected exchanges. Using binary session types, the channels $c$ and $c'$ in the example above would have the types $c : ?\tau.\text{end}$ and $c' : !\tau.\text{end}$, where $?T$ and $!T$ denotes a value of type $T$ is sent or received, respectively. Moreover, the types of $c$ and $c'$ are duals—when one does a send the other does a receive and vice versa. From these types one can describe the sequence and type of the data that is passed around over the channels.

While session types provide a compact way of specifying the behaviour of channels, they can only be used to talk about the type of data that is being passed around—not their payloads. There has been some work by Bocchi et al. [2010] to attach logical predicates to session types to say more about the payloads, however their logic is first-order and a lot of effort is put into keeping type checking decidable. Actris, the logic introduced in this paper, makes no such constraints and allows one to talk more about the payloads, however their logic is first-order and a lot of effort is put into keeping type checking decidable.

Actris inherently captures some features of conventional session types that normally require additional language primitives. One such example is the delegation of channels as seen in

\[
\begin{align*}
\text{let} \ (c, c') &= \text{new\_chan} () \text{ in fork} \ \{\text{send} \ c' (\text{ref} \ 42)\}; \! (\text{recv} \ c)
\end{align*}
\]

This program has the same specification as $\text{prog}_1$, but the dependent separation protocols differ:

\[
\begin{align*}
c &\mapsto ?\ell \langle \ell \mapsto 42 \rangle.\text{end} \quad \text{and} \quad c' &\mapsto !\ell \langle \ell \mapsto 42 \rangle.\text{end}
\end{align*}
\]

This protocol denotes that the endpoints exchange a reference $\ell$, as well as a points-to connective $\ell \mapsto 42$ that describes the ownership and value of the reference $\ell$. To perform the exchange, $c'$ then has to give up ownership of the location, while $c$ acquires it—which is why it can then safely dereference the received location to obtain the expected value.

Furthermore, Actris inherently captures some features of conventional session types that normally require additional language primitives. One such example is the delegation of channels as seen in
the following program:

\[
\text{prog}_3 \triangleq \begin{array}{l}
\text{let } (c_1, c'_1) = \text{new} \_\text{chan} () \text{ in} \\
\text{fork} \{ \text{let } (c_2, c'_2) = \text{new} \_\text{chan} () \text{ in } \text{send } c'_1 \! c_2 ; \text{send } c'_2 (\text{ref } 42) ; \\
!(\text{recv} (\text{recv} c_1)) \}
\end{array}
\]

The specification of the program remains the same as \text{prog}_1 and \text{prog}_2, while the dependent separation protocols change as follows (we omit the dual protocols for the endpoints \(c'_1\) and \(c'_2\)):

\[
c_1 \rightarrow ? c \langle c \rangle \{ c \rightarrow ! \ell \langle \ell \rangle \{ \ell \rightarrow 42 \}. \text{end} \}. \text{end} \quad \text{and} \quad c_2 \rightarrow ? \ell \langle \ell \rangle \{ \ell \rightarrow 42 \}. \text{end}
\]

The protocol states that the exchanged value must be a channel endpoint with the specified protocol, meaning that \(c'_1\) must give up the ownership of the channel thereby delegating it.

Dependent separation protocols \(\overline{x} : \tilde{\tau} \langle \tilde{\nu} \rangle \{ \tilde{P} \}. \text{prot} \) and \(\overline{x} : \tilde{\tau} \langle \tilde{\nu} \rangle \{ \tilde{P} \}. \text{prot} \) are dependent, meaning that the tail \(\text{prot}\) can be defined in terms of the previously quantified variables \(\overline{x} : \tilde{\tau} \). A sample program showing the use of such dependency is:

\[
\text{prog}_4 \triangleq \begin{array}{l}
\text{let } (c, c') = \text{new} \_\text{chan} () \text{ in} \\
\text{fork} \{ \text{let } x = \text{recv} c' \text{ in } \text{send } c' (x + 2) ; \\
\text{send } c 40 ; \text{recv } c \}
\end{array}
\]

This program exchanges a value, adds 2 to it and exchanges it again. As previously, the program specification remains the same, while the dependent separation protocol is defined as:

\[
c \rightarrow ! x \langle x \rangle \{ \text{True} \}. ? \langle x + 2 \rangle \{ \text{True} \}. \text{end}
\]

This protocol explicitly states that the second exchanged value is exactly the first with 2 added to it. These dependencies are not limited to first-order data, but can also be used in combination with functions. Consider:

\[
\text{prog}_5 \triangleq \begin{array}{l}
\text{let } (c, c') = \text{new} \_\text{chan} () \text{ in} \\
\text{fork} \{ \text{let } f = \text{recv} c' \text{ in } \text{send } c' (\lambda (). f() + 2) ; \\
\text{let } r = \text{ref } 40 \text{ in } \text{send } c (\lambda () . ! r) ; \text{recv } c ()
\end{array}
\]

This program, like the one before it, exchanges a value to which 2 is added, but postpones the evaluation by wrapping the computation in a closure. Like before, the program specification remains the same, with the dependent separation protocol being defined as:

\[
c \rightarrow ! P Q \langle f \rangle \{ \{ P \} f () \{ \nu . \nu \in \mathbb{Z} \ast Q(\nu) \} \}. ? g \langle g () \{ \nu . \exists w . (\nu = w + 2) \ast Q(\nu) \} \rangle \}. \text{end}
\]

The \(!\) does not just bind the function value \(f\), but also the precondition \(P\) and postcondition \(Q\) of its Hoare triple. In the second message, a Hoare triple is returned that maintains the original pre- and postconditions, but returns 2 more. This example demonstrates that the state space of dependent separation protocols can be higher-order—it is indexed by the precondition \(P\) and postcondition \(Q\) of \(f\)—which means that they do not have to be agreed upon when creating the protocol.

While it has not been captured in the above examples, protocols are closed under composition, branching, and guarded recursion. It is worth noting that using dependent recursive protocols, one can keep track of a history of what actions have been performed, which, as will be shown, is especially useful when combining channels with locks.

Although Actris is loosely based on session types, its focus is on proving functional correctness of programs that combine message passing with other paradigms. To enable such proofs, the protocols in Actris are defined using arbitrary separation logic predicates, which means that proof checking is necessarily undecidable—Actris is thus not a type system. Furthermore, as a consequence of the focus on functional correctness, Actris does not satisfy properties such as deadlock freedom of session type systems, but it does imply session fidelity through safety (Theorem 5.1).
1.3 Contributions and Outline

This paper introduces Actris: a higher-order impredicative concurrent separation logic build on top of the Iris framework for reasoning about functional correctness of message-passing programs that combine higher-order functions, higher-order references, fork-based concurrency, and locks. Concretely, this paper makes the following contributions:

- We introduce dependent separation protocols inspired by affine binary session types to model the transfer of resources (including higher-order functions) between channel endpoints. We show that they can be used to handle branching, recursion, and delegation (Section 2).
- We demonstrate the benefits obtained from building Actris on top of Iris by showing how Iris’s support for ghost state and locks can be used to prove functional correctness of programs using manifest sharing, i.e., channel endpoints shared by multiple parties (Section 3).
- We provide a case study on Actris and its mechanisation in Coq by proving functional correctness of a variant of the map-reduce algorithm by Dean and Ghemawat [2004] (Section 4).
- We give a model of Actris in the Iris framework using a continuation-passing style (CPS) encoding of dependent separation protocols. Using this model we prove safety (i.e., session fidelity) and postcondition validity of our Hoare triples (Section 5).
- We provide a full mechanisation of Actris using the interactive theorem prover Coq [Hinrichsen et al. 2019]. On top of that, we provide tactics for symbolic execution of dependent separation protocols and mechanise all the examples in the paper (Section 6).

2 A TOUR OF ACTRIS

This section demonstrates the core features of Actris. We first introduce the language (Section 2.1) and the logic (Section 2.2). We then introduce and iteratively extend a simple distributed merge sort algorithm to demonstrate the main features of Actris (Section 2.3–2.8). Note that as the point of the sorting algorithms is to showcase the features of Actris. They are intentionally kept simple and no effort has been made to make them efficient (e.g., to avoid spawning threads for small jobs).

2.1 The Actris Language

The language used throughout the paper is an untyped functional language with higher-order functions, higher-order mutable references, fork-based concurrency, and primitives for message-passing over bidirectional asynchronous channels. The syntax is as follows:

$$
v \in \text{Val} ::= () | i | b | \ell | c | \lambda x. e | \ldots \quad (i \in \mathbb{Z}, b \in \mathbb{B}, c \in \text{Chan}, \ell \in \text{Loc})$$

$$e \in \text{Expr} ::= v | x | \text{rec } f(x) = e | e_1(e_2) | \text{ref } e | ! e | e_1 \leftarrow e_2 | \text{fork } \{e\} | \text{new\_chan } () | \text{send } e_1 e_2 | \text{recv } e | \ldots$$

We omit the usual operations on pairs, sums, lists, and integers, which are standard. We introduce the following syntactic sugar: lambda abstractions $\lambda x. e$ are defined as $\text{rec } \_ (x) = e$, let-bindings $\text{let } x = e_1 \text{ in } e_2$ are defined as $(\lambda x. e_2) e_1$, and sequencing $e_1; e_2$ is defined as $\text{let } \_ = e_1 \text{ in } e_2$.

The language features the usual operations for heap manipulation. New references can be created using $\text{ref } e$, dereferenced using $! e$, and assigned to using $e_1 \leftarrow e_2$. Concurrency is supported via $\text{fork } \{e\}$, which spawns a new thread $e$ that is executed in the background. The language also supports atomic operations like compare-and-set, which can be used to implement lock-free data structures and synchronisation primitives, but these are omitted from the syntax.

The language supports message passing through bidirectional channels, which are represented using pairs of buffers $(\vec{v}_1, \vec{v}_2)$ of unbounded size. The $\text{new\_chan } ()$ operation creates a new channel whose buffers are empty, and returns a tuple of endpoints $(e_1, e_2)$. Bidirectionality is obtained by having one endpoint receive from the other’s send buffer and vice versa. That means, $\text{send } e_1 v$
enqueues the value \( v \) in its own buffer, i.e., \( \bar{v}_1 \), and \( \text{recv} \ c_i \) dequeues a value from the other buffer, i.e., from \( \bar{v}_2 \) if \( i = 1 \) and from \( \bar{v}_1 \) if \( i = 2 \). Message passing is asynchronous, meaning that \( \text{send} \ c \ v \) will always reduce, while \( \text{recv} \ c \) will block as long as the receiving buffer is empty.

Throughout the paper, we often use the following syntactic sugar to encapsulate the common behaviour of starting a new process:

\[
\text{start} \ e \triangleq \text{let } f = e \text{ in let } (c, c') = \text{new-chan}() \text{ in fork } \{ f \ c' \}; c
\]

Here, \( e \) should evaluate to a function that takes a channel endpoint.

### 2.2 The Actris Logic

Actris is a higher-order impredicative concurrent separation logic with a new notion called dependent separation protocols to reason about message-passing concurrency. As we will show in Section 5, Actris is built as a library on top of the Iris framework [Jung et al. 2016, 2018b, 2015; Krebbers et al. 2017a] and thus inherits all features of Iris. For the purpose of this section, no prior knowledge of Iris is expected as the majority of its features are orthogonal. At this point, we are primarily concerned with Iris’s support for nested Hoare triples and guarded recursion, which we need to transfer functions over channels (Section 2.4) and to define recursive protocols (Section 2.6). An extensive overview of Iris can be found in [Jung et al. 2018b].

The grammar of Actris and a selection of its rules are displayed in Figure 1. The Actris grammar includes the polymorphic \( \lambda \)-calculus\(^1\) with a number of primitive types and terms operating on these types. Most important is the type \( \text{iProp} \) of propositions and the type \( \text{iProto} \) of dependent separation protocols. The typing judgement is mostly standard and can be derived from the use of meta variables—we use the meta variables \( P \) and \( Q \) for propositions, the meta variable \( \text{prot} \) for protocols, the meta variable \( v \) for values, and the meta variables \( t \) and \( u \) for general terms of any type. Apart from that, there is the implicit side-condition that recursive predicates defined using the recursion operator \( \mu x : \tau. \ t \) should be guarded. That means, the variable \( x \) should appear under a contractive term construct. As is usual in logics with guarded recursion [Nakano 2000], the later *-modality is contractive so one can define recursive predicates. But other than that, as we will demonstrate in Section 2.6, the constructors of \( ! \bar{x} : \bar{\tau} \langle v \rangle \{ P \} \cdot \text{prot} \) and \( ? \bar{x} : \bar{\tau} \langle v \rangle \{ P \} \cdot \text{prot} \) of dependent separation protocols are contractive in the arguments \( P \) and \( \text{prot} \) to enable the construction of recursive protocols. The rule \( \mu \text{-UNFOLD} \) says that \( \mu x : \tau. \ t \) is in fact a fixpoint of \( t \).

In order to express program specifications, Actris features Hoare triples \( \{ P \} \ e \{ v, Q \} \), where \( P \) is the precondition and \( Q \) the postcondition. The binder \( v \) can be used to talk about the return value of \( e \) in the postcondition \( Q \), but may be omitted whenever the result is \( () \). Note that Hoare triples are propositions of the logic themselves (i.e., they are of type \( \text{iProp} \)), so they can be nested to express specifications of higher-order functions. The rules for Hoare triples are mostly standard, but it is worth pointing out the rule \( \text{HT-REC} \) for recursive functions. This rule has a later *-modality in the precondition, which when combined with the \( \text{Löb} \) rule allows one to reason about general recursive functions. As usual, the points-to connective \( \ell \mapsto v \) expresses unique ownership of a location \( \ell \) with value \( v \). Since we consider a garbage collected language, one can discard arbitrary separation logic resources via the rule \( \text{AFFINE} \).

The novel feature of Actris is its support for dependent separation protocols to reason about message-passing programs. This is done using the \( c \mapsto \text{prot} \) connective, which expresses unique ownership of a channel endpoint \( c \) and states that the endpoint follows the protocol \( \text{prot} \). Dependent separation protocols \( \text{prot} \) are streams of \( ! \bar{x} : \bar{\tau} \langle v \rangle \{ P \} \cdot \text{prot} \) and \( ? \bar{x} : \bar{\tau} \langle v \rangle \{ P \} \cdot \text{prot} \) constructors, ultimately terminated by an \( \text{end} \) constructor. The value \( v \) denotes the message that is being sent (!)

\(^1\)Actris and Iris, which are both formalised as a shallow embedding in Coq, have in fact a predicative Type hierarchy, while propositions \( \text{iProp} \) are impredicative. For brevity’s sake, we omit details about predicativity of Type, as they are standard.
Grammar:
\[
\tau, \sigma ::= x \mid 0 \mid 1 \mid \mathbb{B} \mid \mathbb{N} \mid \mathbb{Z} \mid \text{Type} \mid \forall x : \tau. \sigma \\
\text{Chan} \mid \text{Loc} \mid \text{Val} \mid \text{Expr} \mid i\text{Prop} \mid i\text{Proto} \mid \ldots
\]
\[
t, u, P, Q, \text{prot} ::= x \mid \lambda x : \tau. t \mid t(u) \mid t(\tau) \mid (\text{Polymorphic \(\lambda\)-calculus})
\]
\[
\text{True} \mid \text{False} \mid P \land Q \mid P \lor Q \mid P \Rightarrow Q \mid (\text{Propositional logic})
\]
\[
\forall x : \tau. P \mid \exists v : \tau. P \mid t = u \mid (\text{Higher-order logic with equality})
\]
\[
\mu x : \tau. t \mid \ast P \mid (\text{Guarded recursion})
\]
\[
P \ast Q \mid P \Rightarrow Q \mid \ell \mapsto v \mid \{P\} e \{v. Q\} \mid (\text{Separation logic})
\]
\[
c \mapsto \text{prot} \mid \overline{\text{prot}} \mid \text{prot} \cdot \text{prot} \mid \text{end} \mid (\text{Dependent separation protocols})
\]

Ordinary affine separation logic:

\[
\text{Affine } P \ast Q \Rightarrow P \quad \text{HT-frame } \{P\} e \{w. Q\} \quad \text{HT-val } \{\text{True}\} v \{w. w = v\} \quad \text{HT-fork } \{P\} \text{ fork } \{e\} \{w. w = ()\}
\]
\[
\text{HT-bind } \{P\} e \{v. Q\} \quad \forall v. \{Q\} K[v] \{w. R\} \quad \{P\} K[e] \{w. R\} \quad K \text{ a call-by-value evaluation context}
\]

Recursion:

\[
\text{HT-rec } \{\text{\(\Rightarrow P\)}\} e[v/x][\text{rec} f(x) = e/f] \{w. Q\} \quad \text{\(\Lob\)} \quad \mu\text{-unfold } \mu x. t = t[\mu x. t/x]
\]

Heap manipulation:

\[
\text{HT-alloc } \{\text{\(\text{True}\)}\} \text{ ref } v \{\ell. \ell \mapsto v\} \quad \text{HT-load } \{\ell \mapsto v\} \ell \mapsto w \{\ell \mapsto w\} \quad \text{HT-store } \{\ell \mapsto v\} \ell \leftarrow w \{\ell \mapsto w\}
\]

Message passing:

\[
\{\text{\(\text{True}\)}\} \text{ new_chan } () \{\{c, c'\}. c \mapsto \text{prot} \ast c \mapsto \overline{\text{prot}}\} \quad \text{\(\text{HT-newchan}\)}
\]
\[
\{c \mapsto !\overline{x} : \overline{\tau} \langle v \rangle \{P\}. \text{prot} \ast P[I/\overline{x}]\} \text{ send } c (v[I/\overline{x}]) \{c \mapsto \text{prot}[I/\overline{x}]\} \quad \text{\(\text{HT-send}\)}
\]
\[
\{c \mapsto ?\overline{x} : \overline{\tau} \langle v \rangle \{P\}. \text{prot}\} \text{ recv } c \{w. \exists \overline{x}. (v = w) \ast c \mapsto \text{prot} \ast P\} \quad \text{\(\text{HT-recv}\)}
\]

Dependent separation protocols:

\[
1\overline{x} : \overline{\tau} \langle v \rangle \{P\}. \text{prot} = ?\overline{x} : \overline{\tau} \langle v \rangle \{P\}. \text{prot} \quad (1\overline{x} : \overline{\tau} \langle v \rangle \{P\}. \text{prot}_1 \ast \text{prot}_2 = 1\overline{x} : \overline{\tau} \langle v \rangle \{P\}. (\text{prot}_1 \ast \text{prot}_2))
\]
\[
?\overline{x} : \overline{\tau} \langle v \rangle \{P\}. \text{prot} = !\overline{x} : \overline{\tau} \langle v \rangle \{P\}. \text{prot} \quad (?\overline{x} : \overline{\tau} \langle v \rangle \{P\}. \text{prot}_1 \ast \text{prot}_2 = ?\overline{x} : \overline{\tau} \langle v \rangle \{P\}. (\text{prot}_1 \ast \text{prot}_2))
\]
\[
\text{end} = \text{end} \quad \text{end} \ast \text{prot} = \text{prot} \quad \text{prot} \ast \text{end} = \text{prot} \quad \text{prot}_1 \ast \text{prot}_2 = \text{prot}_1 \ast \text{prot}_2 \quad \text{prot}_1 \ast (\text{prot}_2 \ast \text{prot}_3) = (\text{prot}_1 \ast \text{prot}_2) \ast \text{prot}_3
\]

Fig. 1. The grammar and a selection of rules of Actris.
or received (?), the proposition $P$ denotes the ownership that is transferred along the message, and $prot$ denotes the protocol that describes the subsequent messages. The binders $\tilde{x} : \tilde{\tau}$ can be used to bind variables in $v$, $P$, and $prot$. For example, $\lambda(b : \mathcal{B}) (\ell : \mathsf{Loc}) (i : \mathbb{N}) \{(b, \ell) | (\ell \mapsto i * 10 < i)\}$. $prot$ expresses that a pair of a Boolean and an integer reference whose value is at least 10 is sent. We often omit the proposition $\{P\}$, which simply means it is True.

Apart from the constructors for dependent separation protocols, Actris provides two primitive operations. The $\mathsf{prot}$ connective denotes the dual of a protocol. As with conventional session types, it transforms the protocol by changing all sends (!) into receives (?), and vice versa. Taking the dual twice thus results in the original protocol. The connective $prot_1 : prot_2$ composes the protocols $prot_1$ and $prot_2$, which is achieved by substituting any $\mathsf{end}$ in $prot_1$ with $prot_2$.

The rule $\mathsf{Ht-newchan}$ allow ascribing any protocol to newly created channels using $\mathsf{new-chan}()$, obtaining ownership of $c \mapsto \mathsf{prot}$ and $c' \mapsto \mathsf{prot}$ for the respective endpoints. The duality of the protocol guarantees that any receive is matched with a send by the dual endpoint, which is crucial for establishing safety (i.e., session fidelity, see Section 5.3).

The rule $\mathsf{Ht-send}$ for $\mathsf{send} \ c \ w$ requires the head of the dependent separation protocol of $c$ to be a send (!) constructor, and the value $w$ that is send to match up with the value ascribed by the protocol. Concretely, to send a message, one need to give up ownership of $c \mapsto !\tilde{x} : \tilde{\tau}(v)\{P\}$. $prot$, pick an appropriate instantiation $\tilde{t}$ for the quantified variables $\tilde{x} : \tilde{\tau}$ so that $\tilde{t}[\tilde{t}/\tilde{x}] = w$, and give up ownership of the associated resources $P[\tilde{t}/\tilde{x}]$. Subsequently, one gets back ownership of the protocol $prot[\tilde{t}/\tilde{x}]$ that advanced to the next step.

The rule $\mathsf{Ht-rev}$ for $\mathsf{recv} \ c$ is essentially dual to the rule $\mathsf{Ht-send}$. One needs to give up ownership of $c \mapsto ?\tilde{x} : \tilde{\tau}(v)\{P\}$. $prot$, and in return gets back a value $w$ and resources $P$ that adhere to the protocol. Note that when receiving resources the bound variables are existentially quantified, as the recipient has no knowledge about the exact values that were sent.

### 2.3 Basic Protocols

In order to show the basic features of dependent separation protocols, we will prove the functional correctness of a simple distributed merge sort algorithm, whose code is shown in Figure 2.

The function $\mathsf{sort\_client}$ takes a comparison function $\mathsf{cmp}$ and a reference to a linked list $l$ that will be sorted using merge sort. The bulk of the work is done by the $\mathsf{sort\_service}$ function that is parameterised by a channel $c$ over which it receives a reference to the linked list to be sorted. If the list is an empty or singleton list, which is trivially sorted, the function immediately sends back the unit value () and terminates. Otherwise, the list is split using the $\mathsf{split}$ function into two partitions, which changes the reference $\ell$ to point to the first partition, and returns a reference $\ell'$ that point to the second partition. These partitions are recursively sorted using two newly started instances of $\mathsf{sort\_service}$. The result of the processes are then requested and merged using the $\mathsf{merge}$ function, which updates the reference $l$ to point to the merged list. Finally, a unit value () is sent back along the original channel $c$ to inform the caller that the work has been completed.

In order to verify the correctness of the sorting algorithm we first need a specification for the comparison function $\mathsf{cmp}$, which must satisfy the following specification:

$$
\mathsf{cmp\_spec} \ (I : T \rightarrow \mathsf{Val} \rightarrow \mathsf{iProp}) \ (R : T \rightarrow T \rightarrow \mathcal{B}) \ (\mathsf{cmp} : \mathsf{Val}) \triangleq \\
\forall x_1 x_2 v_1 v_2. \ \{I x_1 v_1 * I x_2 v_2\} \ \mathsf{cmp} v_1 v_2 \ \{r. \ r = R x_1 x_2 * I x_1 v_1 * I x_2 v_2\}
$$

Here, $R$ is a decidable relation on an implicit polymorphic type $T$, and $I$ is an interpretation predicate that relates language values to elements of type $T$. While the relation $R$ dictates the ordering, the interpretation predicate $I$ allows for flexibility with what is ordered. Setting $I$ to $\lambda x. v. \ v \mapsto x$, for instance, orders references by what they point to in memory, rather than the memory address itself.
### 2.4 Transferring Functions

The distributed `sort_service` from the previous section (Figure 2) is parametric on a comparison function. To demonstrate Actris’s support for reasoning about functions transferred over channels, we verify the correctness of the program `sort_service_func` in Figure 3, which receives the comparison function over the channel instead of via a lambda abstraction. In order to verify this program, we extend the protocol `sort_prot` by first sending the comparison function and then continuing as normal. Note that the new protocol includes the quantifications of the functional specification of the comparison function `cmp`, including the polymorphic type `T`, the relation `R`,...
We will now use branching and recursion to verify the correctness of a sorting service that supports multiple sorting jobs in sequence. The code of the sorting service sort_service_{rec} and a possible client sort_client_{rec} can be found in Figure 4. The service sort_service_{rec} contains a loop in which branching is used to either terminate the service, or to sort an individual list using dependent separation protocols. Branching is encoded in terms of sending and receiving a Boolean value that is matched using an if-then-else construct:

\[
\begin{align*}
\text{branch } e \text{ with left } &\Rightarrow e_1 \mid \text{ right } \Rightarrow e_2 \text{ end } \triangleq \text{ if recv } e \text{ then } e_1 \text{ else } e_2 \\
\end{align*}
\]

We also let \( \text{left } \triangleq \text{ true} \) and \( \text{right } \triangleq \text{ false} \) to be used together with \text{select} for the sake of readability. Due to the higher-order nature of Actris, the usual protocol specifications for branching from session types can be encoded as regular logical branching within the protocols:

\[
\begin{align*}
\text{prot}_1 \{Q_1\} \oplus \{Q_2\} \text{ prot}_2 &\triangleq !(b : \mathbb{B}) (b) \{\text{if } b \text{ then } Q_1 \text{ else } Q_2\}. \text{if } b \text{ then } \text{prot}_1 \text{ else } \text{prot}_2 \\
\text{prot}_1 \{Q_1\} \& \{Q_2\} \text{ prot}_2 &\triangleq !(b : \mathbb{B}) (b) \{\text{if } b \text{ then } Q_1 \text{ else } Q_2\}. \text{if } b \text{ then } \text{prot}_1 \text{ else } \text{prot}_2 \\
\end{align*}
\]

We often omit the conditions \( Q_1 \) and \( Q_2 \), which simply means that they are True. The following rules can be directly derived from the rules \text{HT-send} and \text{HT-recv}:

\[
\begin{align*}
\text{HT-select} \\
\{c \mapsto \text{prot}_1 \{Q_1\} \oplus \{Q_2\} \text{ prot}_2\} \text{ select } c \ b \{c \mapsto \text{if } b \text{ then } \text{prot}_1 \text{ else } \text{prot}_2 * \text{ if } b \text{ then } Q_1 \text{ else } Q_2\} \\
\end{align*}
\]

Apart from branching on Booleans values, one can use dependent separation protocols to encode branching on any enumeration type (e.g., lists, natural numbers, days of the week, etc.).

2.6 Recursive Protocols

We will now use branching and recursion to verify the correctness of a sorting service that supports performing multiple sorting jobs in sequence. The code of the sorting service sort_service_{rec} and a possible client sort_client_{rec} can be found in Figure 4. The service sort_service_{rec} contains a loop in which branching is used to either terminate the service, or to sort an individual list using dependent separation protocols. Branching is encoded in terms of sending and receiving a Boolean value that is matched using an if-then-else construct:

\[
\begin{align*}
\text{branch } e \text{ with left } &\Rightarrow e_1 \mid \text{ right } \Rightarrow e_2 \text{ end } \triangleq \text{ if recv } e \text{ then } e_1 \text{ else } e_2 \\
\end{align*}
\]

We also let \( \text{left } \triangleq \text{ true} \) and \( \text{right } \triangleq \text{ false} \) to be used together with \text{select} for the sake of readability. Due to the higher-order nature of Actris, the usual protocol specifications for branching from session types can be encoded as regular logical branching within the protocols:

\[
\begin{align*}
\text{prot}_1 \{Q_1\} \oplus \{Q_2\} \text{ prot}_2 &\triangleq !(b : \mathbb{B}) (b) \{\text{if } b \text{ then } Q_1 \text{ else } Q_2\}. \text{if } b \text{ then } \text{prot}_1 \text{ else } \text{prot}_2 \\
\text{prot}_1 \{Q_1\} \& \{Q_2\} \text{ prot}_2 &\triangleq !(b : \mathbb{B}) (b) \{\text{if } b \text{ then } Q_1 \text{ else } Q_2\}. \text{if } b \text{ then } \text{prot}_1 \text{ else } \text{prot}_2 \\
\end{align*}
\]

We often omit the conditions \( Q_1 \) and \( Q_2 \), which simply means that they are True. The following rules can be directly derived from the rules \text{HT-send} and \text{HT-recv}:

\[
\begin{align*}
\text{HT-select} \\
\{c \mapsto \text{prot}_1 \{Q_1\} \oplus \{Q_2\} \text{ prot}_2\} \text{ select } c \ b \{c \mapsto \text{if } b \text{ then } \text{prot}_1 \text{ else } \text{prot}_2 * \text{ if } b \text{ then } Q_1 \text{ else } Q_2\} \\
\end{align*}
\]

Apart from branching on Booleans values, one can use dependent separation protocols to encode branching on any enumeration type (e.g., lists, natural numbers, days of the week, etc.).
We let
\[ J \]
which, similar to
\[ \Box \]
\[ \text{The protocol uses the branching operator} \oplus \text{to specify that the client may either request the service to perform a sorting job, or terminate communication with the service. After the job has been finished, the protocol dictates that one can proceed recursively.} \]
\[ \text{It is important to point out that—as is usual in logics with guarded recursion [Nakano 2000]—the variable} x \text{should appear under a contractive term construct in} \mu x : \tau \cdot t. \text{In our protocol, the recursive variable} \text{rec appears under the argument of} \oplus, \text{which is defined in terms of} !x : ?(v)\{P\}, \text{prot, which, similar to}? x : ?(v)\{P\}. \text{prot, is contractive in the arguments} P \text{and prot.} \]
\[ \text{The specifications of the service and the client are as follows:} \]
\[ \text{sort}_\text{client}_{\text{rec}} (\text{cmp} l \triangleq \text{let} c = \text{start sort}_\text{service}_{\text{rec}} (\text{cmp} \in \text{iter} (\lambda l'. \text{select} c \text{left;} \text{send} c l'; \text{recv} c) l; \text{select} c \text{right}) \]
\[ \text{sort}_\text{service}_{\text{rec}} (\text{cmp} c \triangleq \text{branch} c \text{with} \]
\[ \text{end} \]
\[ \text{left} \Rightarrow \text{sort}_\text{service} (\text{cmp} c); \]
\[ \text{sort}_\text{service}_{\text{rec}} (\text{cmp} c) \]
\[ \text{right} \Rightarrow () \]
\[ \text{sort}_\text{client}_{\text{rec}} (\text{cmp} l \triangleq \text{let} c = \text{start sort}_\text{service}_{\text{rec}} (\text{cmp} \in \text{iter} (\lambda l'. \text{select} c \text{left;} \text{send} c l'; \text{recv} c) l; \text{select} c \text{right}) \]
\[ \text{sort}_\text{service}_{\text{rec}} (\text{cmp} c \triangleq \text{branch} c \text{with} \]
\[ \text{end} \]
\[ \text{left} \Rightarrow \text{sort}_\text{service} (\text{cmp} c); \]
\[ \text{sort}_\text{service}_{\text{rec}} (\text{cmp} c) \]
\[ \text{right} \Rightarrow () \]
\[ \text{Fig. 4. A recursive version of the sort service that can perform multiple jobs in sequence.} \]
\[ \text{The protocol uses the branching operator} \oplus \text{to specify that the client may either request the service to perform a sorting job, or terminate communication with the service. After the job has been finished, the protocol dictates that one can proceed recursively.} \]
\[ \text{It is important to point out that—as is usual in logics with guarded recursion [Nakano 2000]—the variable} x \text{should appear under a contractive term construct in} \mu x : \tau \cdot t. \text{In our protocol, the recursive variable} \text{rec appears under the argument of} \oplus, \text{which is defined in terms of} !x : ?(v)\{P\}, \text{prot, which, similar to}? x : ?(v)\{P\}. \text{prot, is contractive in the arguments} P \text{and prot.} \]
\[ \text{The specifications of the service and the client are as follows:} \]
\[ \text{sort}_\text{service}_{\text{rec}} (I : T \rightarrow \text{Val} \rightarrow \text{iProp}) \text{and} \text{sort}_\text{service}_{\text{rec}} (R : T \rightarrow T \rightarrow \text{B}) \triangleq \mu (\text{rec} : \text{iProto}). (\text{sort}_\text{prot} R \cdot \text{rec}) \oplus \text{end} \]
\[ \text{The protocol uses the branching operator} \oplus \text{to specify that the client may either request the service to perform a sorting job, or terminate communication with the service. After the job has been finished, the protocol dictates that one can proceed recursively.} \]
\[ \text{It is important to point out that—as is usual in logics with guarded recursion [Nakano 2000]—the variable} x \text{should appear under a contractive term construct in} \mu x : \tau \cdot t. \text{In our protocol, the recursive variable} \text{rec appears under the argument of} \oplus, \text{which is defined in terms of} !x : ?(v)\{P\}, \text{prot, which, similar to}? x : ?(v)\{P\}. \text{prot, is contractive in the arguments} P \text{and prot.} \]
\[ \text{The specifications of the service and the client are as follows:} \]
\[ \{\text{cmp}_\text{spec} I R \text{cmp} * c \Rightarrow \text{sort}_\text{prot}_{\text{rec}} \cdot \text{prot} \} \text{and} \{\text{cmp}_\text{spec} I R \text{cmp} * \ell \Rightarrow \exists \tilde{x} \} \]
\[ \text{\{sort}_\text{service}_{\text{rec}} \text{cmp c} \Rightarrow \exists \tilde{y}, \tilde{\tilde{y}} \Rightarrow \tilde{x} \Rightarrow \ell \Rightarrow \exists \tilde{y} \Rightarrow (\forall i < |\tilde{x}|. \text{sorted}_\text{of}_R \tilde{y} i \tilde{\tilde{y}})) \}
\[ \text{We let} f \triangleq \lambda \ell' \tilde{y}, \ell' \rightarrow f \tilde{y} \text{to express that} \ell \text{points to a list of lists} \tilde{x}. \text{The proof of the service follows naturally by symbolic execution using the induction hypothesis (obtained from Lön), the rules} \text{HT-Branch} \text{and} \text{HT-Select}, \text{and the specification of} \text{sort}_\text{service}. \text{Note that we rely on the specification of} \text{sort}_\text{service} \text{having an arbitrary protocol as its post-composition.} \]
\[ \text{It is worth pointing out that protocols in Actris provide a lot of flexibility. Using just minor changes, we can extend the protocol to support transferring a comparison function over the channel, like the extension made in} \text{sort}_\text{client}_{\text{func}}, \text{or in a way that a different comparison function can be used for each sorting job.} \]

### 2.7 Delegation

Delegation is a common feature within communication protocols, and particularly the session-types community—it is the concept of transferring a channel endpoint over a channel. Due to the impredicativity of protocols in Actris, reasoning about programs that make use of delegation is readily available. The protocols ![x : ?(v){P}, prot] and ![x : ?(v){P}, prot] can simply refer to the ownership of protocols ![x \Rightarrow prot'] in the proposition P.
sort_service_{del} cmp c \triangleq 
\begin{align*}
\text{branch } c & \text{ with} \\
\text{left} & \Rightarrow \\
& \text{let } c' = \text{start sort_service cmp in} \\
& \text{send } c c' \\
& \text{sort_service}_{\text{del}} cmp c \\
| \text{right} & \Rightarrow () \\
\end{align*}

\begin{align*}
\text{sort_client}_{\text{del}} cmp l = & \text{let } c = \text{start sort_service}_{\text{del}} cmp in \\
& \text{let } k = \text{new_list } () \text{ in} \\
& \text{iter } (\lambda l'. \text{select } c \text{ left}; \\
& \text{let } c' = \text{recv } c \text{ in} \\
& \text{push } c' k; \text{ send } c' l') l \\
& \text{send } c \text{ right}; \\
& \text{iter } \text{recv } k
\end{align*}

Fig. 5. A recursive version of the sort service that uses delegation to perform multiple jobs in parallel.

An example of a program that uses delegation is the sort_service_{del} variant of the recursive sorting service in Figure 5, which allows one to perform multiple sorting jobs in parallel. To enable parallelism, it delegates a new channel c’ to an inner sorting service for each sorting job.

The client sort_client_{del} once again uses the sorting service to sort a nested linked list l of linked lists. The client starts a connection c to the new service, and for each inner list l’, it acquires a delegated channel c’, over which it sends a pointer l’ to the inner list that should be sorted. The client keeps track of all channels to delegated services in a linked list k so that it can wait for all of them to finish (using iter recv).

A protocol for the delegation service can be defined as follows, denoting that the client can select whether to acquire a connection to delegated service or to terminate:

\[
\text{sort_prot}_{\text{del}} (I : T \to Val \to iProp) (R : T \to T \to \mathbb{B}) \triangleq \\
\mu ( rec : iProto). (? (c : Chan) \langle c \to \text{sort_prot } I R \rangle. \text{rec} ) \oplus \text{end}
\]

The specifications of the service client are as follows:

\[
\begin{align*}
& \{ \text{cmp_spec } I R \text{ cmp } * \} \\
& \{ \text{c } \to \text{sort_prot}_{\text{del}} \cdot \text{ prot } \} \\
& \{ \text{sort_service}_{\text{del}} \text{ cmp } c \} \\
& \{ \text{c } \to \text{ prot } \}
\end{align*}
\]

\[
\begin{align*}
& \{ \text{cmp_spec } I R \text{ cmp } * \ell \leftrightarrow j \overrightarrow{y} \} \\
& \{ \text{sort_client}_{\text{del}} \text{ cmp } \ell \}
\end{align*}
\]

As before, we let \( J \triangleq \lambda \ell'. \ell' \mapsto i \overrightarrow{y} \) to express that \( \ell \) points to a list of lists \( \overrightarrow{x} \). Once again the proofs are straightforward, as it is simply a combination of a recursive reasoning combined with the application of Actris’s rules for channels.

### 2.8 Dependent Protocols

The protocols we have seen so far have only made limited use of Actris’s support for recursion. We now demonstrate Actris’s support for dependent protocols, that make it possible to keep track of the history of what messages have been sent and received. We demonstrate this feature by considering a fine-grained version of the distributed merge sort service. This version sort_service_{fg}, as shown in Figure 6, requires the input list to be sent element by element, after which the service sends the sorted list back in the same fashion. We use branching to indicate whether the whole list has been sent (right) or whether another element remains to be sent (left).

The structure of sort_service_{fg} is somewhat similar to the coarse-grained merge-sort algorithm that we have seen before. The base cases of the empty or the singleton list are handled initially. This is achieved by waiting for at least two values before starting the recursive sub-services \( c_1 \) and \( c_2 \). In the base cases the values are sent back immediately, as they are trivially sorted.
The inductive case is handled by starting two sub-services $c_1$ and $c_2$ that are respectively sent the two initially received elements, after which the split function is used to receive and forward the remaining values to the sub-services alternatingly. Once the right flag is received, the split function terminates, and the algorithm moves to the second phase in which the merge function merges the stream of values returned by the sub-services and forwards them to the parent service.

The merge function initially acquires the first value $x$ from the first sub-service, which it uses in the recursive call as the current largest value. The recursive procedure merge aux recursively requests a value $y$ from the sub-service of which the current largest value was not acquired from. It then compares $x$ and $y$ using the comparison function $cmp$, and forwards the smallest element. This is repeated until the right flag is received from either sub-service, after which the remaining values of the other are forwarded to the parent service using the transfer function.

The interface of the client sort client for this service is similar to the previous ones. It takes a reference to a linked list, which is then sorted. It performs this task by sending the elements of
the linked list to the sort service using the send_all function, and puts the received values back into the linked list using the recv_all function.

A suitable protocol for proving functional correctness of the fine-grained sorting service is:

\[
\begin{align*}
\text{sort}_\text{prot}_\text{head}^\text{fg} &= (I : T \to \text{Val} \to \text{iProp}) (R : T \to T \to \text{B}) \triangleq \mu (\text{sort}_\text{prot}_\text{head}^\text{fg} I R) e \\
\text{sort}_\text{prot}_\text{head}^\text{fg} &= \lambda \bar{x}. ((x : T) (v : \text{Val}) \langle v \rangle \{ I x v \}. \text{rec} \ (\bar{x} \cdot [x])) \ \ominus \ \text{sort}_\text{prot}_\text{tail}^\text{fg} \ I R \bar{x} e \\
\text{sort}_\text{prot}_\text{tail}^\text{fg} &= (I : T \to \text{Val} \to \text{iProp}) (R : T \to T \to \text{B}) \triangleq \mu (\text{rec} : \text{List} T \to \text{iProto}). \\
\lambda \bar{x} \bar{y}. (? (y : T) (v : \text{Val}) \langle v \rangle \{ (\forall i < |\bar{y}|. R \bar{y}_i y) \ast I y v \}. \text{rec} \ (\bar{x} \cdot [y])) \ (\text{True}) \ & \ (\bar{x} \equiv_p \bar{y}) \end{align*}
\]

The protocol is split into two phases \text{sort}_\text{prot}_\text{head}^\text{fg} and \text{sort}_\text{prot}_\text{tail}^\text{fg}, mimicking the behaviour of the program. The \text{sort}_\text{prot}_\text{head}^\text{fg} phase is indexed by the values \bar{x} that have been sent so far. The protocol describes that one can either send another value and proceed recursively, or stop, which moves the protocol to the next phase.

The \text{sort}_\text{prot}_\text{tail}^\text{fg} phase is dependent on the list of values \bar{x} received in the first phase, and the list of values \bar{y} returned so far. The condition \((\forall i < |\bar{y}|. R \bar{y}_i y) \ast I y v\) states that the received element is larger than any of the elements that have previously been returned, which maintains the invariant that the stream of received elements is sorted. When the right flag is received \(\bar{x} \equiv_p \bar{y}\) shows that the received values are a permutation of the ones that were sent, making sure that all of the sent elements have been accounted for.

The top-level specification of the service and client are similar to the specifications of the coarse grained version of distributed merge sort:

\[
\begin{align*}
\{ \text{cmp} \_ \text{spec} \ I R \text{cmp} \ast c \ \Rightarrow \ \text{sort}_\text{prot}_\text{fg} \cdot \text{prot} \} & \quad \{ \text{cmp} \_ \text{spec} \ I R \text{cmp} \ast c \ \mapsto \ \text{sort}_\text{prot}_\text{fg} \cdot \text{prot} \} \\
\{ \text{sort}_\text{prot}_\text{fg} \ c \ \mapsto \ c \} & \quad \{ \text{sort}_\text{client}_\text{fg} \ c \mapsto \ I \bar{x} \} \\
\{ \exists \bar{y} \cdot \bar{y} \mapsto \text{sort}_\text{fg} \ 	ext{of}_R \bar{y} \bar{x} \} & \quad \{ \exists \bar{y} \cdot \bar{y} \mapsto \text{sort}_\text{fg} \ 	ext{of}_R \bar{y} \bar{x} \} \\
\end{align*}
\]

Proving these specifications requires one to pick appropriate specifications for the auxiliary functions to capture the required invariants with regard to sorting. After having picked these specifications, the parts of the proofs that involve communication are mostly straightforward, but require a number of trivial auxiliary results about sorting and permutations.

3 MANIFEST SHARING VIA LOCKS

Since dependent separation protocols and the connective \(c \mapsto \text{prot}\) for ownership of protocols are first-class objects of the Actris logic, they can be used like any other logical connective. This means that protocols can be combined with any logical mechanism that Actris inherits from Iris. In particular, they can be combined with Iris’s generic invariant and ghost state mechanism, and can be used in combination with Iris’s abstractions for reasoning about other concurrency connectives like locks, barriers, lock-free data structures, etc.

In this section we demonstrate how dependent separation protocols can be combined with lock-based concurrency. This combination allows us to prove functional correctness of programs that make use of the notion of manifest sharing [Balzer and Pfenning 2017], where channel endpoints are shared between multiple parties. Instead of having to extend Actris, we make use of locks and ghost state that Actris readily inherits from Iris. We present the basic idea with a simple introductory example of sharing a channel endpoint between two parties (Section 3.1). We then consider a more challenging example of a distributed load-balancing mapper (Section 3.2).
Actris: Session-Type Based Reasoning in Separation Logic

\[
\begin{align*}
&\{R\} \text{new\_lock} () \{lk. \text{is\_lock} lk R\} \quad \text{(HT-new-lock)} \\
&\{\text{is\_lock} lk R\} \text{acquire} lk \{R\} \quad \text{(HT-acquire)} \\
&\{\text{is\_lock} lk R * R\} \text{release} lk \{\text{True}\} \quad \text{(HT-release)} \\
&\text{is\_lock} lk R \Rightarrow \text{is\_lock} lk R * \text{is\_lock} lk R \quad \text{(LOCK-DUP)}
\end{align*}
\]

Fig. 7. The rules Actris inherits from Iris for locks.

\[
\text{prog\_lock} \triangleq \text{let } c = \text{start} (\lambda c. \text{let } lk = \text{new\_lock} () \text{ in} \\
\quad \text{fork} \{\text{acquire} lk; \text{send} c 21; \text{release} lk\}; \\
\quad \text{acquire} lk; \text{send} c 21; \text{release} lk) \text{ in} \\
\quad \text{recv} c + \text{recv} c
\]

Fig. 8. A sample program that combines locks and channels to achieve manifest sharing.

3.1 Locks and Ghost State

Using the language from Section 2.1 one can implement locks using a spin lock, ticket lock, or a more sophisticated implementation. For the purpose of this paper, we abstract over the concrete implementation and assume that we have operations \text{new\_lock}, \text{acquire} and \text{release} that satisfy the common separation logic specifications for locks as shown in Figure 7.

The \text{new\_lock} () operation creates a new lock, which can be thought of as a mutex. The operation \text{acquire} lk will atomically take the lock or block in the case the lock is already taken, and \text{release} lk releases the lock so that it may be acquired by other threads. The specifications in Figure 7 make use of the representation predicate \text{is\_lock} lk R, which expresses that a lock \(lk\) guards the resources described by the proposition \(R\). When creating a new lock one has to give up ownership of \(R\), and in turn, obtains the representation predicate \text{is\_lock} lk R (HT-new-lock). The representation predicate can then be freely duplicated so it can be shared between multiple threads (LOCK-DUP). When entering a critical section using \text{acquire} lk, a thread gets exclusive ownership of \(R\) (HT-acquire), which has to be given up when releasing the lock using \text{release} lk (HT-release). The resources \(R\) that are protected by the lock are therefore invariant in-between any of the critical sections.

To show how locks can be used, consider the program in Figure 8, which uses a lock to share a channel endpoint between two threads that each send the integer 21 to the main thread. The following dependent protocol, where \(n\) denotes the number of messages that should be exchanged, captures the expected interaction from the point of view of the main thread:

\[
\text{lock\_prot} (n : \mathbb{N}) \triangleq \text{if } n = 0 \text{ then end } \text{else } ?(21).\text{lock\_prot} (n - 1)
\]

Since \(c \mapsto \text{lock\_prot} n\) is an exclusive resource, we need a lock to share it between the threads that send 21. For this we will use the following lock invariant:

\[
\text{is\_lock} lk (\exists n. \text{auth} \_n * c \mapsto \text{lock\_prot} n)
\]

The natural number \(n\) is existentially quantified since it changes over time depending on the values that are sent. To tie the number \(n\) to the number of contributions made by the threads that share the channel endpoint, we make use of the connectives \text{auth}\_n and \text{contrib}\_n, which are defined using Iris’s “ghost theory” mechanism for “user-defined” ghost state [Jung et al. 2018b, 2015].

The \text{auth}\_n fragment can be thought of as an authority that keeps track of the number of ongoing contributions \(n\), while each \text{contrib}\_n is a token that witnesses that a contribution is still in progress.
True ⇒ ∃γ. authγ 0                                          (Auth-init)
authγ n ⇒ contribγ * authγ (1 + n)                           (Auth-alloc)
authγ (1 + n) * contribγ ⇒ authγ n                          (Auth-dealloc)
authγ n * contribγ ↣ n > 0                                  (Auth-contrib-pos)

Fig. 9. The authoritative contribution ghost theory.

These concepts are made precise by the rules in Figure 9. The rule Auth-init expresses that an
authority authγ 0 can always be created, which is given some fresh ghost identifier γ. Using the
rules Auth-alloc and Auth-dealloc, one can allocate and deallocate tokens contribγ as long as the
count n of ongoing contributions in authγ n is updated accordingly. The rule Auth-contrib-pos expresses that ownership of a token contribγ implies that the count n of authγ n must be positive.

Most of the rules in Figure 9 involve the logical connective ⇛ of a so-called view shift. The
view shift connective, which Actris inherits from Iris, can be though of as a "ghost update", which
is made precise by the structural rules Vs-csq and Vs-frame rules, that establish the connection
between ⇛ and the Hoare triples of the logic:

\[
\begin{align*}
\text{Vs-csq} & : P \Rightarrow P' \quad \{P'\} e \{v. Q'\} \quad \forall v. Q' \Rightarrow Q \\
\text{Vs-frame} & : P \Rightarrow Q \\
& \quad \{P\} e \{v. Q\} \\
& \quad P * R \Rightarrow Q * R
\end{align*}
\]

With the ghost state in place, we can now state suitable specifications for the program. The
specification of the top-level program is shown on the right, while the left Hoare triple shows the
auxiliary specification of both threads that send the integer 21:

\{
contribγ * is_lock lk (\exists n. authγ n * c ↣ lock_prot n)}
acquire lk; send c 21; release lk
\{
True \}

\{
True \}

To establish the initial lock invariant, we use the rules Auth-init and Auth-alloc to create the
authority authγ 2 and two contribγ tokens. The contribγ tokens play a crucial role in the proofs
of the sending threads to establish that the existentially quantified variable n is positive (using
Auth-contrib-pos). Knowing n > 0, these threads can establish that the protocol lock_prot n has
not terminated yet (i.e., is not end). This is needed to use the rule Ht-send to prove the correctness of
sending 21, and thereby advance the protocol from lock_prot n to lock_prot (n − 1). Subsequently,
these threads can deallocate the token contribγ (using Auth-dealloc) and restore the lock invariant.

3.2 A Distributed Load-Balancing Mapper

This section demonstrates a more interesting use of manifest sharing by showing how Actris can be
used to verify functional correctness of a distributed load-balancing mapper that maps a function f
over a list. Our distributed mapper consists of one client that distributes the work, and a number of
workers that perform the function f on individual elements x of the list. To enable communication
between the client and the workers, we make use of a single channel. One endpoint is used by the
client to distribute the work between the workers, while the other endpoint is shared between all
workers to request and return work from the client. The implementation of the workers, which can
be found in Figure 10, consists of a loop over three phases:
mapper_worker f, lk c ≜
acquire lk; select c left;
branch c with
  right ⇒ release lk
| left ⇒ let x = recv c in release lk;
  let y = f v x in
  acquire lk; select c right; send c y; release lk;
mapper_worker f, lk c

Fig. 10. A worker of the distributed mapper service.

True ⇒ ∃γ. auth γ 0 ∅
(authM-init)
auth γ n X ⇒ auth γ (1 + n) X * contrib γ ∅
(authM-alloc)
auth γ n X * contrib γ ∅ ⇒ auth γ (n - 1) X
(authM-dealloc)
auth γ n X * contrib γ Y ⇒ auth γ n (X ⊔ Z) * contrib γ (Y ⊔ Z)
(authM-add)
auth γ Z ⊆ Y * auth γ n X * contrib γ Y ⇒ auth γ n (X \ Z) * contrib γ (Y \ Z)
(authM-remove)
auth γ n X * contrib γ Y ⇒ n > 0 * Y ⊆ X
(authM-contrib-agree)
auth γ 1 X * contrib γ Y ⇒ Y = X
(authM-contrib-agree1)

Fig. 11. The authoritative contribution ghost theory extended with multisets.

(1) The worker notifies the client that it wants to perform work (using select c left), after which it is then notified (using branch) whether there is more work or all elements have been mapped. If there is more work, the worker receives an element x that needs to be mapped. Otherwise, the worker will terminate.

(2) The worker maps the function f on x.

(3) The worker notifies the client that it wants to send back a result (using select c right), and subsequently sends back the result y of mapping f on x.

The first and last phases are in a critical section guarded by a lock lk since they involve interaction over a shared channel endpoint. As the sharing is encapsulated by the worker, we omit the code of the client for brevity’s sake.2

A protocol that describes the interaction from the client’s point of view is as follows:

mapper_prot (IT : T → Val → iProp) (IU : U → Val → iProp) (f : T → List U) ≜
μ (rec : N → MultiSet T → iProto). λ n X.
  if n = 0 then end else
  !(x : T) (v : Val) ≜ \{IT x v\}. rec n (X ⊔ {x}) ⊕ rec (n - 1) X
  ⟨(n=1)⇒(X=∅)&{True}⟩
  ? (x : T) (ℓ : Loc) ⟨ℓ⟩. x ∈ X * ℓ ⊆ IU (f x). rec n (X \ {x})

The protocol is parameterised by representation predicates IT and IU that relate language values to elements of type T and U in the logic, as well as a function f : T → List U that specifies the

2The interested reader can find the entire code in the accompanied Coq development [Hinrichsen et al. 2019].
behaviour of the language-level function \( f_v \). The connection between \( f \) and \( f_v \) is formalised as:

\[
\begin{align*}
\text{f_spec} \ (I_T : T \rightarrow \text{Val} \rightarrow \text{iProp}) \ (I_U : U \rightarrow \text{Val} \rightarrow \text{iProp}) \ (f : T \rightarrow \text{List } U) \ (f_v : \text{Val}) & \triangleq \\
\forall x. v. \ {\{I_T \times v\} f_v \ y} \ \{\ell. \ \ell \mapsto_I {I_U} \ f \ x\}
\end{align*}
\]

Similar to `lock_prot` from Section 3.1, `mapper_prot` is indexed by the number of remaining workers \( n \). On top of that, it carries a multiset \( X \) describing the values currently being processed by all the workers. The multiset \( X \) is used to make sure that the returned results are in fact the result of mapping the function \( f \). The condition \((n = 1) \Rightarrow (X = \emptyset)\) on the branch \& expresses that the last worker may only request more work if there are no ongoing jobs.

To accommodate sharing the channel endpoint between all workers using a lock invariant, we need to extend the connectives of the authoritative contribution ghost theory from Section 3.1 to \( \text{auth}_v n \ X \) and \( \text{contrib}_v Y \), making them include multisets \( X \) and \( Y \) that keep track of the values held by the workers. The rules for the ghost theory extended with multisets are shown in Figure 11. The rules `AuthM-init`, `AuthM-alloc` and `AuthM-dealloc` are straightforward generalisations of the ones we have seen before. The new rules `AuthM-add` and `AuthM-remove` determine that the multiset \( Y \) of \( \text{contrib}_v Y \) can be updated as long as it is done in accordance with the multiset \( X \) of \( \text{auth}_v n \ X \). Finally, the `AuthM-contrib-agree` rule expresses that the multiset \( Y \) of \( \text{contrib}_v Y \) must be a subset of the multiset \( X \) of \( \text{auth}_v n \ X \), while the stricter rule `AuthM-contrib-agree1` asserts equality between \( X \) and \( Y \) when only one contribution remains.

The specifications of `mapper_worker` and a possible top-level client `mapper_client` that uses \( n \) workers to map \( f_v \) over the linked list \( \ell \) are as follows:

\[
\begin{align*}
\{ \text{f_spec } I_T & \ I_U \ f \ f_v \ * \ \text{contrib}_v \emptyset \ * \ \\
\text{is_lock } & \ y \ \exists n \ X. \ \text{auth}_v n \ X \ * \\
\text{mapper_worker } & \ f_v \ \text{lk} \ c \ \\
\text{True}\}
\end{align*}
\]

\[
\begin{align*}
\{ \text{f_spec } I_T & \ I_U \ f \ f_v \ * \ \\
\text{mapper_client } & \ n \ f_v \ \ell \ \\
\exists y. \ y & \equiv \text{flatMap} \ f \ x \ * \ \ell \mapsto_I \ U \ y\}
\end{align*}
\]

The lock invariant and specification of `mapper_worker` are similar to those used in the simple example in Section 3.1. The specification of `mapper_client` \( n \ f_v \ \ell \) simplifies to states that the resulting linked list points to a permutation of performing the map at the level of the logic. To specify that, we make use of `flatMap`: \((T \rightarrow \text{List } U) \rightarrow (\text{List } T \rightarrow \text{List } U)\), whose definition is standard.

The proof of the client involves allocating the channel with the protocol `mapper_prot` \( I_T \ I_U \ f \ n \), where \( n \) is the initial number of workers. Subsequently, we use the rules `AuthM-init` and `AuthM-alloc` to create the authority \( \text{auth}_v n \ \emptyset \) and \( n \) tokens \( \text{contrib}_v \emptyset \), which allow us to establish the lock invariant and to distribute the tokens among the mappers. The proof of the mapper proceeds as usual. After acquiring the lock, the mapper obtains ownership of the lock invariant. Since the worker owns the token \( \text{contrib}_v \emptyset \), it knows that the number of remaining workers \( n \) is positive, which allows it to conclude that the protocol has not terminated (i.e., is not \text{end}). After using the rules for channels, the rules `AuthM-add` and `AuthM-remove` are used to update the authority, to reestablish the lock invariant so the lock can be released.

## 4 CASE STUDY: MAP-REDUCE

As a means of demonstrating the use of Actris for verifying more realistic programs, we present a proof of functional correctness of a simple distributed load-balancing implementation of the map-reduce model by Dean and Ghemawat [2004].

Since Actris is not concerned with distributed systems over networks, we consider a version of map-reduce that distributes the work over forked-off threads on a single machine. This means that
we do not consider mechanics like handling the failure, restarting, and rescheduling of nodes that a
version that operates on a network has to consider.

In order to implement and verify our map-reduce version we make use of the implementation and
verification of the fine-grained distributed merge sort algorithm (Section 2.8) and the distributed
load-balancing mapper (Section 3.2). As such, our map-reduce implementation is mostly a suitable
client that glues together communication with these services. The purpose of this section is to
give a high-level description of the implementation, the actual code and proofs can be found in the
accompanied Coq development [Hinrichsen et al. 2019].

4.1 A Functional Specification of Map-Reduce

The purpose of the map-reduce model is to transform an input set of type List $T$ into an output set
of type List $V$ using two functions $f$ (often called “map”) and $g$ (often called “reduce”):

$$f : T \rightarrow \text{List} (K \ast U) \quad g : (K \ast \text{List} U) \rightarrow \text{List} V$$

An implementation of map-reduce performs the transformation in three steps:

1. First, the function $f$ is applied to each element of the input set. This results in lists of key/value
   pairs which are then flattened using a $\text{flatMap}$ operation (an operation that takes a list of
   lists and appends all nested lists):

   $$\text{flatMap} f : \text{List} T \rightarrow \text{List} (K \ast U)$$

2. Second, the resulting lists of key/value pairs are grouped together by their key (this step is
   often called “shuffling”):

   $$\text{group} : \text{List} (K \ast U) \rightarrow \text{List} (K \ast \text{List} U)$$

3. Finally, the grouped key/value pairs are passed on to the $g$ function, after which the results
   are flattened to aggregate the results. This again is done using a $\text{flatMap}$ operation:

   $$\text{flatMap} g : \text{List} (K \ast \text{List} U) \rightarrow \text{List} V$$

The complete functionality of map-reduce is equivalent to applying the following $\text{map\_reduce}$ function on the entire data set:

$$\text{map\_reduce} : \text{List} T \rightarrow \text{List} V \triangleq (\text{flatMap} g) \circ \text{group} \circ (\text{flatMap} f)$$

A standard instance of map-reduce is counting word occurrences, where we let $T \triangleq K \triangleq \text{String}$
and $U \triangleq \mathbb{N}$ and $V \triangleq \text{String} \ast \mathbb{N}$ with:

$$f : \text{String} \rightarrow \text{List} (\text{String} \ast \mathbb{N}) \triangleq \lambda x. \ [(x, 1)]$$
$$g : (\text{String} \ast \text{List} \mathbb{N}) \rightarrow \text{List} (\text{String} \ast \mathbb{N}) \triangleq \lambda (k, \bar{n}). \ [(k, \Sigma_{i < |\bar{n}|} i, \bar{n}_i)]$$

4.2 Implementation of Map-Reduce

The general distributed model of map-reduce is achieved by distributing the phases of mapping,
shuffling, and reducing, over a number of worker nodes (e.g., nodes of a cluster or individual CPUs).
To perform the computation in a distributed way, there is some work involved in coordinating the
jobs over these worker nodes, which is usually done as follows:

1. Split the input data into chunks and delegate these chunks to the mapper nodes, that each
   apply the “map” function $f$ to their given data in parallel.
2. Collect the complete set of mapped results and “shuffle” them, i.e., group them by key. The
   grouping is commonly implemented using a distributed sorting algorithm.
3. Split the shuffled data into chunks and delegate these chunks to the reducer nodes that each
   apply the “reduce” function $g$ to their given data in parallel.
(4) Collect and aggregate the complete set of result of the reducers.

Our variant of the map-reduce model is defined as a function $\text{map\_reduce}_v n m f_v g v \ell$, which coordinates the work for performing map-reduce on a linked list $\ell$ between $n$ mappers performing the “map” function $f_v$ and $m$ workers performing the “reduce” function $g_v$. To make the implementation more interesting, we prevent storing intermediate values locally by forwarding/returning them immediately as they are available/requested. The global structure is as follows:

1. Start $n$ instances of the load-balancing $\text{mapper\_worker}$ from Section 3, parameterised with the $f_v$ function. Additionally start an instance of $\text{sort\_service}_{fg}$ from Section 2, parameterised by a concrete comparison function on the keys, corresponding to $\lambda (k_1, \_)(k_2, \_). k_1 < k_2$. Note that the type of keys are restricted to be $\mathbb{Z}$ for the sake of brevity.

2. Perform a loop that handles communication with the mappers. If the mapper request work, pop a value from the input list. If the mapper returns work, forward it to the sorting service. This process is repeated until all inputs have been mapped and been forwarded to the sorting service.

3. Start $m$ instances of the $\text{mapper\_worker}$, parameterised by $g_v$.

4. Perform a loop that handles communication with the mappers. If the mapper request work, group elements returned by the sort service. If the mapper returns work, aggregate the returned value in a the linked list. Grouped elements are created by requesting and aggregating elements from the sorter until the key changes.

The aggregated linked list then contains the fully mapped input set upon completion.

### 4.3 Functional Correctness of Map-Reduce

The specification of the program is as follows:

$$\{ 0 < n \ast 0 < m \ast f\_spec_{I_T I_Z \ast U} f f_v \ast f\_spec_{I_Z \ast \text{List} U} I_V g g_v \ast \ell \mapsto_{I_T} \overline{x} \}$$

$$\text{map\_reduce}_v n m f_v g_v \ell$$

$$\{ \exists \overline{z}. \overline{z} \equiv_p \text{map\_reduce}_v f g \overline{x} \ast \ell \mapsto_{I_V} \overline{z} \}$$

The $f\_spec$ predicates (as introduced in Section 3.2) establish a connection between the functions $f$ and $g$ on the logical level and the functions $f_v$ and $g_v$ in the language. These make use of the various interpretation predicates $I_T, I_Z \ast U, I_Z \ast \text{List} U, \text{and } I_V$ for the types in question. Lastly, the $\ell \mapsto_{I_T} \overline{x}$ predicate determines that the input is a linked list of the initial type $T$. The postcondition asserts that the result $\overline{z}$ is a permutation of the original linked list $\overline{x}$ applied to the functional specification $\text{map\_reduce}_v$ of map-reduce from Section 4.1.

### 5 THE MODEL OF ACTRIS

Actris is defined as an internal logic embedded in the Iris framework [Jung et al. 2016, 2018b, 2015; Krebbers et al. 2017a]. This means that the type of $i\text{Proto}$ of dependent separation protocols and the connective $c \mapsto prot$ for the ownership of a channel endpoint are merely definitions in the Iris logic, and that the Actris proof rules are merely lemmas in the Iris logic. In this section we describe the interesting aspects of this embedding. First, we present our definitional semantics of bidirectional channels (Section 5.1). We then show how the type $i\text{Proto}$ is modelled using a continuation-passing style (CPS) interpretation (Section 5.2). Finally, we show how adequacy (safety and postcondition validity of Hoare triples) follows the embedding into Iris (Section 5.3). Apart from the foundational advantages of building Actris on top of Iris, as shown in this section, we will furthermore see that it has practical advantages in Section 6—we can readily reuse Iris’s Coq infrastructure.
5.1 Semantics of Channels

Since the Iris framework is parametric in the programming language that is being used, there are various approaches to add support for channels:

- One could instantiate Iris with a language that has native support for channels. This approach was taken in the original Iris paper [Jung et al. 2015] and by Tassarotti et al. [2017].
- One could implement channels using an existing language that Iris has been instantiated with. Bizjak et al. [2019] carried out this approach for a lock-free implementation of channels.

In this paper we went for the second approach. We used HeapLang, the default concurrent language shipped with Iris, and implemented bidirectional channels using a pair of linked-lists protected by a lock. Although this implementation is not efficient, it has the benefit that it gives a clear declarative semantics that corresponds exactly to the intuitive semantics given in Section 2.1.

At the level of the logic, the state of both buffers of a bidirectional channel is described using the representation predicate \( (c_1, c_2) \mapsto (\bar{v}_1, \bar{v}_2) \). We prove Jacobs and Piessens [2011]-style logically atomic specifications that roughly correspond to the following Hoare triples:

\[
\begin{align*}
\{ \text{True} \} & \text{ new_chan } () \ ( (c_1, c_2), (c_1, c_2) \mapsto (e, e) ) \\
\{ (c_1, c_2) \mapsto (\bar{v}_1, \bar{v}_2) \} & \text{ send } c_1 \ ( (c_1, c_2) \mapsto (w \cdot [\bar{v}_1], \bar{v}_2) ) \\
\{ (c_1, c_2) \mapsto (\bar{v}_1, \bar{v}_2) \} & \text{ send } c_2 \ ( (c_1, c_2) \mapsto (\bar{v}_1, w \cdot [\bar{v}_2]) ) \\
\{ (c_1, c_2) \mapsto (\bar{v}_1, \bar{v}_2) \} & \text{ recv } c_1 \ ( w \cdot (\bar{v}_1 = [w] \cdot \bar{w}) \cdot (c_1, c_2) \mapsto (\bar{w}, \bar{v}_2) ) \\
\{ (c_1, c_2) \mapsto (\bar{v}_1, \bar{v}_2) \} & \text{ recv } c_2 \ ( w \cdot (\bar{v}_2 = [w] \cdot \bar{w}) \cdot (c_1, c_2) \mapsto (\bar{v}_1, \bar{w}) )
\end{align*}
\]

In Section 5.3 we show how Actris’s rules for channels (\( \text{Ht-newchan}, \text{Ht-send} \) and \( \text{Ht-recv} \)) are derived from these logically atomic specifications. It is worth pointing out that the embedding of Actris only makes use of these specifications, and thus abstracts from the implementation details of the channel. This means that the channel implementation could be replaced with a more efficient version, or with a version that is built natively into the language.

5.2 The Model of Dependent Separation Protocols

Dependent separation protocols are intuitively streams of \( !\bar{x} : \bar{\tau} \langle \nu \rangle \{ P \} \). \( \text{prot} \) and \( ?\bar{x} : \bar{\tau} \langle \nu \rangle \{ P \} \). \( \text{prot} \) nodes, that are either infinite, or terminated by an \( \text{end} \). What makes them different from ordinary streams, that are commonly defined as coinductive data types, is the sequence of binders \( \bar{x} : \bar{\tau} \). These binders are higher-order and impredicative, meaning they can range over any type of Iris, including functions, propositions, predicates, and protocols themselves. Since Iris readily supports higher-order and impredicative quantification (in \( \forall \) and \( \exists \)) we wish to reuse that functionality. To do so, we define the type \( \text{iProto} \) in continuation-passing style (CPS) as follows:

\[
\begin{align*}
\text{iProto} \doteq & \ 1 + (\exists \nu \cdot (\text{Val} \rightarrow (\downarrow\text{iProto} \rightarrow \text{iProp}) \rightarrow \text{iProp})) \\
\text{end} & \doteq \ \text{inj}_1 () \\
!\bar{x} : \bar{\tau} \langle \nu \rangle \{ P \} \). \text{prot} & \doteq \ \text{inj}_2 (\text{true}, \lambda w (f : \downarrow\text{iProto} \rightarrow \text{iProp})). \exists(\bar{x} : \bar{\tau}). (\nu = w) \ast \rightarrow P \ast f (\text{next} \ \text{prot}) \\
?\bar{x} : \bar{\tau} \langle \nu \rangle \{ P \} \). \text{prot} & \doteq \ \text{inj}_2 (\text{false}, \lambda w (f : \downarrow\text{iProto} \rightarrow \text{iProp})). \exists(\bar{x} : \bar{\tau}). (\nu = w) \ast \rightarrow P \ast f (\text{next} \ \text{prot})
\end{align*}
\]

Ignoring the \( \downarrow \) for the moment, the left part of sum-type indicates that the protocol has terminated, while the right part describes an exchange, where the Boolean indicates whether it is a send or a receive. Send and receive are defined as predicates \( \text{Val} \rightarrow (\downarrow\text{iProto} \rightarrow \text{iProp}) \rightarrow \text{iProp} \) that describe the ownership of the exchange: \( w : \text{Val} \) is the value that is being transferred, and \( f : \downarrow\text{iProto} \rightarrow \text{iProp} \) is a continuation that represents the tail of the protocol.
Note that due to the definition of iProto in CPS form, the recursive occurrence of iProto does not appear in strict positive positions. To define the type we make use of Iris’s support for guarded recursive types, which requires the recursive occurrence to appear below a ▶ construct (whose only constructor is next : T → ▶ T). Guarded recursive types in Iris are internally constructed using America and Rutten [1989]’s theorem for solving recursive domain equations. With the above definition at hand, the dual (·) and composition (_ · _) operations are defined using Iris’s guarded recursion operator μx : τ. t.

5.3 Adequacy of Dependent Separation Protocols

Now that we have given a semantics of channels (Section 5.1) and a model of dependent separation protocols (Section 5.2), it remains to use these concepts to define the c ↔ prot connective, and prove Actris’s Hoare triples for channels (Ht-newchan, Ht-send and Ht-recv). Adequacy of Actris (Theorem 5.1) then follows immediately from Iris’s adequacy theorem.

In order to define Actris’s connectives c1 ↔ prot1 and c2 ↔ prot2 for ownership of channel endpoints, we need to tie prot1 and prot2 to the physical contents of the channel buffers as captured by the representation predicate (c1, c2) ↔ (v1, v2). As a result of duality of the protocols for both endpoints, we are always in one of the two situations:

- There are zero or more messages v1 in transit from the first endpoint to the second. That is, the buffer contents is (c1, c2) ↔ (v1, ◦), and prot2 starts with a series of receive (?) nodes that match up with the contents v1 of the first buffer.
- There are zero or more messages v2 in transit from the second endpoint to the first. That is, the buffer contents is (c1, c2) ↔ (◦, v2), and prot1 starts with a series of receive (?) nodes that match up with the contents v2 of the second buffer.

This intuitive idea can be formalised in Iris as follows:

$$\text{interp } \epsilon \text{ prot}_1 \text{ proto}_2 \triangleq (\text{prot}_1 = \overline{\text{prot}_2})$$

$$\text{interp } ([v] \cdot \overline{v}) \text{ proto}_1 \text{ proto}_2 \triangleq \exists \Phi \text{ proto}_2'. (\text{proto}_2 = \text{inj}_2(\text{false}, \Phi)) *$$

$$(\forall (f : \text{iProto} \rightarrow \text{iProp}). f (\text{next proto}_2') \equiv \Phi \epsilon f) *$$

$$\text{interp } \overline{v} \text{ proto}_1 \text{ proto}_2'$$

$$I y_1 y_2 c_1 c_2 \triangleq \exists v_1 v_2 \text{ proto}_1 \text{ proto}_1'. (c_1, c_2) \leftrightarrow (v_1, v_2) *$$

$$y_1 \mapsto \bullet \text{ proto}_1 * y_2 \mapsto \bullet \text{ proto}_2 *$$

$$\vee \left(\left(v_2 = \epsilon * \text{interp } v_1 \text{ proto}_1 \text{ proto}_1 \right) \vee \left(v_1 = \epsilon * \text{interp } v_2 \text{ proto}_2 \text{ proto}_1 \right)\right)$$

$$c \mapsto \text{proto} \triangleq \exists y_1 y_2 c_1 c_2. (\overline{I y_1 y_2 c_1 c_2} *$$

$$(c = c_1 * y_1 \mapsto_\circ \text{proto}) \lor (c = c_2 * y_2 \mapsto_\circ \text{proto})$$

Setting the deeper technicalities aside, the most important parts are as follows. The two situations informally described above are captured by the disjunction in the invariant I. The predicate interp v proto1 proto2 captures that proto2 contains zero or more receive (?) nodes that match up with the values v.

In order to tie c ↔ proto to the contents of the bidirectional channel we follow the usual Iris methodology: we make use of Iris’s invariants connective [R] and a suitable “ghost theory”. The invariant connective [R] expresses that the proposition R holds at any time, i.e., is invariant. As for the ghost theory we use ghost variables γ γ , which express that proto and proto' should be equal at all times. The subtle part of this ghost theory is that it involves ownership of protocols of type iProto, which are defined in terms of Iris propositions iProp, which themselves
are defined in terms of iProto. This circularity is handled using the notion of higher-order ghost state [Jung et al. 2016], which is built into Iris.

With the above definitions at hand, we can now prove the rules $\text{HT-newchan}$, $\text{HT-send}$ and $\text{HT-recv}$ from the combination of the logically atomic specifications in Section 5.1 and Iris’s rules for invariants and ghost state. This gives rise to the main result:

**Theorem 5.1 (Adequacy of Actris).** Let $\phi$ be a first-order predicate over values and suppose the Hoare triple $\{\text{True}\} e \{\phi\}$ is derivable in Actris, then:

- **(Safety):** The program $e$ will not get stuck.
- **(Postcondition validity):** If the main-thread of $e$ terminates with a value $v$, then the postcondition $\phi v$ holds at the meta-level.

Since Actris is an internal logic embedded in Iris, the proof is an immediate consequence of Iris’s adequacy theorem [Jung et al. 2018b; Krebbers et al. 2017a]. Finally, note that safety implies session fidelity—any message that is received has in fact been sent.

### 6 COQ MECHANISATION

The definition of the Actris logic, its model, and the proofs of the examples in this paper have been fully mechanised using the Coq proof assistant [Coq Development Team 2019]. The mechanisation is built on top of the mechanisation of Iris [Jung et al. 2016, 2018b; Krebbers et al. 2017a] and the MoSeL Proof Mode (formerly Iris Proof Mode) [Krebbers et al. 2018, 2017b], which essentially provides an embedded proof assistant for separation logic in Coq. Building Actris on top of the Iris framework in Coq has a number of tangible advantages:

- By defining channels on top of HeapLang, the default concurrent language shipped with Iris, we do not have to define a full programming language semantics and can reuse all of the Coq machinery, including the tactics for symbolic execution of non message-passing programs.
- Since Actris is essentially mechanised as an Iris library that provides support for the iProto type, the $c \rightarrow prot$ connective, the various operations on protocols, and the proof rules as lemmas, we get all present features of Iris for free.
- When proving the Actris proof rules, we can make use of the MoSeL Proof Mode to carry out proofs directly using separation logic, thus reasoning at a high-level of abstraction.
- We can make use of the extendable nature of the MoSeL Proof Mode to define custom tactics for symbolic execution of message-passing programs.

These advantages give rise to a very small Coq development. The total size is about 3500 lines of code (comments and whitespace are included), of which 200 lines are used for the definitional semantics of channels, 1000 lines for the model, 450 lines for tactics, 1250 lines for the examples, and 600 lines for utilities (linked lists, permutations, etc.).

In order to implement Actris’s tactics for symbolic execution, we followed the methodology described in the original Iris Proof Mode paper [Krebbers et al. 2017b], which means that the logic in Coq is presented in weakest precondition style rather than using Hoare triples. For handling $\text{send}$ or $\text{recv}$ we defined the following tactics:

- $\text{wp_send} \left( t1 \ldots tn \right)$ with "[$\mathit{H1} \ldots \mathit{Hn}$]" and $\text{wp_recv} \left( y1 \ldots yn \right)$ as "H".

These tactics roughly perform the following actions:

- Find a $\text{send}$ or $\text{recv}$ in evaluation position of the program under consideration.
- Find a corresponding $c \rightarrow prot$ hypothesis in the separation logic context.
- Normalise the protocol $prot$ using the rules for duals, composition, and fixpoints so it can be written with a $! \bar{x} : \tau \langle \mathit{v}\rangle \{P\}$. $prot$ or $? \bar{x} : \tau \langle \mathit{v}\rangle \{P\}$. $prot$ construct in head position.
• In case of \( \text{wp}\_\text{send} \), instantiate the variables \( \bar{x} : \bar{\tau} \) using the terms \((t_1 \ldots t_n)\), and create a goal for the proposition \( P \) with the hypotheses \([H_1 \ldots H_n]\). Hypotheses prefixed with $ are framed. In case the terms \((t_1 \ldots t_n)\) are omitted, these are determined using unification.
• In case of \( \text{wp}\_\text{recv} \), introduce the variables \( \bar{x} : \bar{\tau} \) into the context by naming them \((y_1 \ldots y_n)\), and create a hypothesis \( H \) for \( P \).

7 RELATED WORK

As Actris combines results from both the separation logic and session types community, it may not come as a surprise that there is an abundance of related work. This section briefly elaborates on the relation to message passing in separation logic (Section 7.1) and process calculi (Section 7.2), session types (Section 7.3), and verification efforts of map-reduce (Section 7.4).

7.1 Message-Passing and Separation Logic

Lozes and Villard [2012] proposed a logic, based on previous work by Villard et al. [2009], to reason about programs written in a small imperative language with message passing using channels similar to ours. Messages are labelled, and protocols are handled with a combination of finite-state automata (FSA) with correspondingly labelled transitions and predicates associated with each state of the automata. This combination is similar to, but less general than, STSs in Iris. Their language does not support higher-order functions or delegation, but since their language is restricted to structured concurrency (i.e., not fork-based) and their logic is linear (i.e., not affine), they ensure that all resources like channels and memory are properly deallocated.

The original Iris [Jung et al. 2015] includes a small message-passing language with channels that do not preserve message order. It was included to demonstrate that Iris is flexible enough to handle other concurrency models than standard shared-memory concurrency. Since the Hoare-triples for send and receive only reason about the entire channel buffer, protocol reasoning must be done via STSs or other forms of ghost state.

Hamin and Jacobs [2019] take an orthogonal direction and use separation logic to prove deadlock freedom of programs that communicate over message passing using a custom logic tailored to this purpose. Contrary to us, their paper does not deal with functional correctness.

Mansky et al. [2017] take yet another direction and verify the functional correctness of a message-passing system written in C using VST [Appel 2014]. While they do not verify message-passing programs like we do, they do verify that the implementation of their message-passing system is resilient to faulty behaviour in the presence of malicious senders and receivers.

The work most closely related to ours, and the only work we know of that combines session types with separation logic, is by Tassarotti et al. [2017] whose main contribution is to prove correctness and termination preservation of a compiler from a simple language with session types to a functional language with mutable state, where the channels are implemented using references on the heap. This work is also done in Iris. The session types they consider are more like standard session types, which cannot express functional properties of messages, but their types.

The Disel logic by Sergey et al. [2018] and the Aneris logic by Krogh-Jespersen et al. [2019] can be used to reason about message-passing programs that work on network sockets. As such, channels can only be used to send strings, are not order preserving, and messages can be dropped but not duplicated. Since only strings are sent over channels complex data (such as functions) must be marshalled and unmarshalled in order to be sent over the network. As such Disel and Aneris address a different use case than we do.
7.2 Separation Logic and Process Calculus

Another approach is to verify message-passing programs written in some dialect of process calculus. We focus on related work that combines process calculus with separation logic.

Francalanza et al. [2011] use separation logic to verify programs written in a CCS-like language. Channels model memory location, which has the effect that their input-actions behave a lot like our updates of mutable state with variable substitutions updating the state. As a proof of concept they prove the correctness of an in-place quick-sort algorithm.

Oortwijn et al. [2016] use separation logic and the mCRL2 process calculus to model communication protocols. The logic itself operates on a high level of abstraction and deals exclusively with intraprocess communication where a fractional separation logic is used to distribute channel resources to concurrent threads. Protocols are extracted from source code, but there is no formal connection between the specification logic and the underlying language.

Neither approach supports delegation or any concurrency paradigms other than message passing.

7.3 Session Types

Our protocols are heavily inspired by binary session types pioneered by Honda et al. [1998]. Session types typically ensure that well-typed systems enjoy certain properties like session fidelity, progression, and deadlock freedom. Moreover, significant effort is placed into keeping type checking decidable. Bocchi et al. [2010] push the boundaries of what can be verified with multi-party session types while staying within a decidable fragment of first-order logic. They use first-order predicates to describe properties of values being sent and received. By imposing restrictions on these predicates, such as ensuring that nothing is sent that will invalidate a future predicate down the line, decidability is maintained. The constraints on the logic does, however, limit what programs can be verified.

One of the key features of session types is that endpoints are owned by a single process and while these can be delegated they cannot be shared. Sharing channels is often desirable, as we demonstrate in Section 3. Balzer and Pfenning [2017] developed a session-typed system with support for manifest sharing, which is the notion of sharing a channel endpoint between multiple actors and use lock-like structure to ensure mutual exclusion in the critical sections. They later expanded the type-system to also guarantee deadlock freedom [Balzer et al. 2019].

7.4 Verification of Map-Reduce

To our knowledge the only verification related to the map-reduce model [Dean and Ghemawat 2004] is by Ono et al. [2011], who made two mechanisations in Coq. The first took a functional model of map-reduce and verified a few specific mappers and reducers, extracted these to Haskell, and ran them using Hadoop Streaming. The second did the same by annotating Java mappers and reducers using JML and proving them correct using the Krakatoa tool [Marché et al. 2004], using a combination of SAT-solvers and the Coq proof assistant. While they worked on verifying specific mappers and reducers, our case study focuses on verifying the communication of a map-reduce model that can later be parameterised with concrete mappers and reducers.

8 FUTURE WORK

One of the most prominent extensions of binary session types is multi-party session types [Honda et al. 2008], often called choreographies, which allow concise specifications of message transfers between more than two parties. It would be interesting to explore a multi-party version of dependent separation protocols, and to determine if there is a translation, similar to the one from multi-party session types into binary session types, for such a version.
In addition to safety (i.e., session fidelity), conventional session type systems guarantee properties like deadlock and resource leak freedom. Since our language supports unstructured fork-based concurrency, establishing such properties is known to be difficult. Recent work by Bizjak et al. [2019], however, provides an approach to prove resource leak freedom of non-structured fork-based concurrent programs using separation logic. It would be interesting to investigate if these ideas could be transferred to Actris to establish the absence of resource leaks. As for establishing deadlock freedom, recent work by Balzer et al. [2019]; Hamin and Jacobs [2019] may provide insights.

Another direction for future work is to use dependent separation protocols for a logical relations model of session types. Similar to the RustBelt project [Jung et al. 2018a], this would give rise to an extensible approach for proving type soundness of type systems with session types, which can be used to establish that unsafe code in libraries has been safely encapsulated by its ADT.
